## ABSTRACT

Pedigree analysis of 29 rice varieties revealed that their origin was traced to 69 ancestors, of which 25 were from India and remaining 44 from 12 different countries. Three ancestors viz., DEE-GEO-WOO-GEN, CINA AND LATISAIL, were common in 24 out of 29 varieties. IR 8 had the highest foot print value followed by Peta indicating their profound influence in the pedigrees of these 29 rice varieties. Pedigree profiles also revealed that 16 out of 29 rice varieties possess genomes of indica, japonica and javanica sub spp. Clustering based on Coefficient of Co-ancestry (CoC) resulted in grouping of two major clusters with 18 and 11 varieties respectively and culminated in the identification of diverse clusters. Finally, the genetic diversity of the 29 short duration rice varieties was observed to be narrow and, therefore, necessary to broaden the genetic base of the present day rice cultivars, by bringing in genes of agronomic values from large germplasm.

Key words: Rice-pedigree, coefficient of co-ancestry, genetic base index, foot print value, inbreeding coefficient

Rice is world's most important food crop that feed over half of the global population. India, where it is planted to 42 mha, has made spectacular progress in rice production and productivity as evidenced from five-fold increase from 21mt in 1950s, to 93mt, in 2006-07 (Shobharani 2010). This was due to the development of high yielding rice varieties (HYV) coupled with adoption of improved cultural practices which heralded the so called "Green revolution". Breakthrough in rice vield was achieved with the development of semi-dwarf varieties characterized by lodging resistance and nitrogen responsiveness (Borlaug 1998). However, on the other side, green revolution led to the depletion of genetic base of rice varieties, as thousands of traditional varieties (landraces) were replaced by a handful of modern rice varieties, resulting in genetic uniformity (Shivkumar et al. 1998; Mishra et al. 2003). Similar situations have been reported from Japan (Kaneda

1985), United States (Dilday 1990), Taiwan (Lin 1991), Latin America (Cuevas-Perez *et al.* 1992) and Australia (Ko *et al.* 1994), documenting a widespread reduction in genetic diversity of modern rice cultivars due to intensive breeding efforts. Therefore, knowledge of genetic relationships among modern rice cultivars is of prime importance to breeders for understanding of germplasm usage to avoid development of varieties with a narrow genetic base (Shivkumar *et al.* 1998; Davierwala *et al.* 2000).

To avoid the pitfalls of narrow genetic base, pedigree information has historically been used to predict performance, compute coefficient of parentage, plan further crosses for cultivar development and trace the inheritance of specific gene variants. Coefficient of parentage (CoP) (Kempthorne *et al.* 1985) or Coefficient of co ancestry (CoC) (Falconer and Mackay 1996) can be calculated from pedigree analysis and may provide alternative or additional measures that quantify relatedness among genotypes. It indirectly measures the genetic diversity among cultivars by estimating from pedigree records, the probability that alleles, in a locus, are identical by descent. The present study was, therefore, undertaken to quantify the genetic base of short duration rice varieties with the objectives of (1) determining Coefficient of Co-ancestry, (2) calculating the genetic contribution of ancestral lines to the genetic diversity of modern rice varieties, (3) to estimating the inbreeding coefficient, foot print value and genetic base index and (4) to identify set of divergent genotypes for further breeding programmes.

#### MATERIALS AND METHODS

#### **Plant materials**

The materials comprised 29 short duration rice varieties maturing in 105-115 days. Of these, 25 are recommended for cultivation in the states of Tamil Nadu and Puducherry during May/June-August/ September seasons. Two varieties *viz.*, Annada and Tulasi, as popular national varieties and another two varieties: IR 72 and IR 74 as popular IRRI varieties (IRRI bred varieties cultivated in many countries) were included for comparison. These rice varieties were bred in different rice research stations of Tamil Nadu Agricultural University, Coimbatore and Peruthalaivar Kamaraj Krishi Vigyan Kendra (PKKVK) of Puducherry (Table 1).

#### **Pedigree data**

Details of ancestors *i.e.*, pareents, grandparents, great grandparents and so on of all the 29 short duration rice varieties were gathered from several sources in the literature (Ghouse *et al.* 1960; Subramanian and Manuel 1998; Sharma and Rao 2004; Shobharani *et al.* 2008) web site (www.iris.irri.org) and from personal communication (Dr. Alcantara Researcher of Data Administration Team, INGER, IRRI Philippines). PEDITREE software package, developed by Vanberloo and Hutten (2005) was used to analyze the pedigree data thus collected. Data were provided in the form of a Microsoft access database containing a single table with the pedigree data. Using peditree software measures of Inbreeding Coefficient (IBC), Coefficient of Co ancestry (CoC) and foot print value were calculated and images of pedigree tree and Pedi graph were also produced. Inbreeding coefficient (IBC), a measure of genetic relatedness within a variety, was estimated using circular edge walking method as suggested by Falconer and MacKay (1996). Coefficient of Co ancestry (CoC), another similar measure of genetic relatedness, but between a pair of varieties, was calculated for all 406 pair wise combinations following the method of Falconer and Mackay (1996). Foot print value is a measure of a genotype indicating its influence in being used as parent in number of crosses. Such influential genotypes were identified by its higher foot print values using progeny batch tab sheet in the Peditree software. Genotypes with large foot print can be considered to have a relatively large input in the complete set of germplasm involved in development of 29 rice varieties.

#### **Genetic Base Index (GBI)**

Genetic base index of the rice varieties can be assessed using inbreeding coefficient and number of ancestors involved in development of a particular variety. It was calculated as follows. Lower the index, broader the genetic base.

$$GBI = \frac{IBC}{Number of ancestors} \times 100$$

## **Pedigree tree**

The PEDITREE results of an each pedigree (variety) search were displayed as an explorer-like collapsible expandable tree, allowing focus on specific parts of the pedigree giving depth of generation etc.,

## **Pedi graph**

Conventional pedigree diagram of each variety was created by exporting data to a Pedi graph data file to visualize very complex pedigree relationships.

## **Cluster analysis**

The coefficient of co ancestry data generated using PEDITREE software was used in the NTSYS-pc software to cluster the rice varieties. A dendrogram was constructed based on a matrix of the coefficients of ancestry. By using an Unweighted Pair Group Method based on Arithmetic mean (UPGMA) with the

SAHN clustering function of NTSYS-pc package.

## **RESULTS AND DISCUSSION**

Unlike morphological, biochemical and molecular markers, pedigree data do not require the observations to be recorded on the plant material and is not influenced by environment or the technique used (Gopal and Oyama 2005). Geneticists can use pedigree information to estimate the genetic distance among cultivars, or to evaluate the contribution of various genetic pools to current cultivars. Applied plant breeders can use this information to identify parents that are genetically dissimilar and thus have the potential to generate new variability for future crop improvement, or to identify genetic pools that have proven valuable

Table 4. Foot print value of some of the genotypes involved

## or have been neglected in the past (Calhoun et al. 1994). Coefficient of parentage (COP), based on pedigree information provides an indirect measure for the relative genetic similarity of related individuals. If the pedigrees are well documented and reliable, the establishment of groups is possible (Smith et al. 1985). Pedigree analysis of 29 rice varieties showed that their origin were traced to 69 ancestors out of which 25 were of Indian origin, contributing 36 per cent of the genes, and the remaining 44 from 12 different countries, contributing 64 per cent of the genes (Table 2,3). In earlier studies, Lin (1991) reported the presence of 65 ancestors in the pedigrees of 99 japonica rice varieties of Taiwan, Shivkumar et al. (1998) observed only 37 ancestors in the development of 29 rice varieties in Kerala and (Joshi 2005) noticed 35 ancestors in the

Table 2. Details of depth of generations, ancestry, sub spp composition, IBC and GBI of rice varieties

\* Sub spp status is not known

evolution of 28 Nepalese rice varieties. Pedigree images of all the 29 varieties were obtained and the image of ADT 37 is shown as an example in Figure 1. Depths of generations indicate number of crossings involved in evolution of a particular variety. Screen shot of the depth of generations for ADT 36 is shown in Figure 2.

In the present study, 31 out of 69 ancestors occurred only once in the pedigree of 29 rice varieties which is similar to that reported earlier (Shivkumar *et al.* 1998) where in 11 out of 37 ancestors appeared only once (Table 2). Further, it was observed that only 18 landraces contributed for the development of more than 10 varieties. DEE-GEO-WOO-GEN was the most frequently used ancestor due to its source of dwarfing gene (sd-1) and it appeared in as many as 25 (86.20 %) varieties. This was followed by CINA and LATISAIL each in 24 (82.70%), for photo periodinsensitivity (used as maternal parent) and for non-

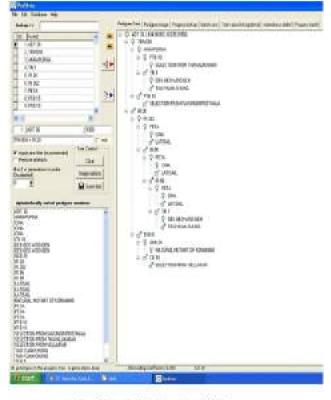

Figure 1. Surroughet of depth of generations of ADT 20.

shattering, respectively. Further GEB 24, for good grain quality, in 20 (69 %) varieties and TSAI- YUAN-CHUNG, for good agronomic base, in 19 (66 %) varieties. It was revealed that three ancestors *viz.*, DEE-GEO-WOO-GEN, CINA and LATISAIL, the parents of IR 8, are common in 24 out of 29 varieties. This is in accordance with the earlier reports of

Joshi (2005). In India out of 298 rice varieties released between 1966 and 1986 by Central Variety Release committee (CVRC), 90 % of the varieties are semidwarf bearing the blood of DEE-GEE-WOO-GEN (Krishnamurthy 1986) while in Cuba, 98 % of rice varieties carry the same semi-dwarfing genes from DEE-GEO-WOO-GEN (Foster and Rutger 1978). In addition, most of these parental varieties used in hybridization programs trace to the same maternal parent: CINA, resulting in a very uniform cytoplasm (Fuentes et al. 1999). It is interesting to note from the pedigree profiles that 16 out of 29 rice varieties possess genomes of indica, japonica and javanica while seven possess indica and japonica only. This in contrast to the finding of Joshi (2005) in pedigree analysis of 28 Nepalese varieties wherein it was reported 27 out of 28 were purely indica genomes only. However, of the 20 wild sp. of rice only O. nivara, source of grassy stunt virus gene (Gsy), was traced as ancestor in 11 out of 29 varieties. Even though 20,000 accessions of wild sp. housed in germplasm banks (Zamir 2001) are sources of resistance to various biotic/ abiotic stresses (Khush 1999) only O. nivara was found utilized in the pedigrees of 29 rice varieties.

Hargrove et al. (1985), Shivkumar et al. (1998) and

Clustering based on Coefficient of Co-ancestry (CoC) resulted in grouping of two major clusters I and II with 18 and 11 varieties respectively (Figure 3). All rice varieties bred at Aduthurai (except ADT 42) and IRRI (except IR 72) were found grouped in Cluster I

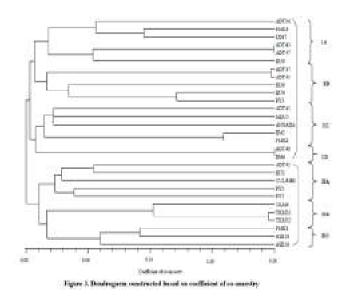

#### Pedigree analysis of short duratio rice

| Sl. | Variety | Parentage                          | Year of release | Breeding station    |

College & Research Instt. NRRI, National Rice Research Institute

while varieties bred at Tirurkuppam and Ambasamudram were observed in Cluster II. Grouping of IRRI lines with ADT lines may be due to more frequent use of IRRI lines as parents in the breeding programmes at Aduthurai rice research station. Further the usage of their own breeding lines/varieties in their breeding programmes may be another reason for clustering together of varieties of particular breeding station. Similar results were earlier reported for clustering Cuban varieties (Fuentes *et al.* 2005) and Indian rice varieties (Davierwala *et al.* 2000). Clustering analysis culminated in the identification of diverse clusters IA (ADT 36, PMK 3, C0 47, ADT 43 ADT 47 and IR 50) and cluster II C (PMK 1, ASD 18 and ASD 16) and hybridization programmes involving these varieties may throw superior segregants besides broadening the genetic base.

Upon skimming of the pedigree data, it was observed that IR 8 had the highest foot print value of 14.38 (Table 4) followed by Peta with 11.25. In a similar study, Davierwala et al. (2000) reported the usage of IR 8, TN 1 and TKM 6 most frequently in the breeding programmes. The influence of IRRI bred varieties/lines was very evident from the fact that IR 8, the miracle rice variety developed during 1966, six years after IRRI was established (Khush 1999), was used directly or indirectly as parent in 19 out of 23 non IRRI bred varieties taken in the present investigation. Further, it indicated that out of 66, 35 were from IRRI which is indicative of the strong influence of IRRI coded lines in the breeding programmes of many rice research stations under National Agricultural Research Systems (NARS).

Inbreeding coefficient (IBC), a measure of genetic relatedness, indicates the presence of genotypes several times in the pedigree of a variety. On the other hand, more the number of ancestors involved in the development of a variety, more its genetic base. IBC alone may not be a reliable measure of genetic base because in certain varieties with few unrepeated ancestors the IBC will be 0.00 indicating broad genetic base. Therefore, by considering both IBC and number of ancestors, a genetic base index (GBI) was worked out. Among 29 varieties studied, PMK 1 (0.011) was found to be genetically broadest followed by ADT 47 (0.016) and TULASHI (0.022) (Table 2). Varieties bred at Aduthurai, compared to other centers, had broad genetic base. Even though genetic base of ADT varieties is broader they are genetically similar owing to sharing of common ancestry. In this study, ADT 43 and ADT 47 are genetically broader because of involvement of more number of ancestors in their pedigrees with lower IBC but they are genetically similar as indicated in the dendrogram (Figure 3) and inferred from the pedigree details of these two varieties (ADT 43 is one of the parents of ADT 47: Table 1).

In conclusion, the genetic diversity of the 29 short duration rice varieties was observed to be narrow and, therefore, it is necessary to broaden the genetic base of the present day rice cultivars, by bringing in genes of agronomic value, resistance to biotic and abiotic stresses from large germplasm comprising landraces and wild spp. Widening the genetic base of rice cultivars can be accelerated by two approaches: (1) Thousands of landraces with wide allelic versions of desirable genes, left hitherto unutilized/underutilized, can be put into use by forming core collections using DNA markers (Xu et al. 2004). This provides breeders access to choose diverse genetic stocks for further hybridization. (2) Gene reserves from wild spp. can also be roped in by offsetting crossability barriers that come in the way of wide hybridization, through tissue culture techniques and constructing introgression Lines (ILs) using molecular markers by backcrossing (Zamir 2001). This ILs, comprising of marker-defined exotic segments of wild spp. introgressed onto the background of elite varieties, enables the breeders to discover and characterize genes that underlie traits of agricultural value.
